Lunar, diel and tidal variability in penaeid prawn larval abundance in the Mandovi estuary, Goa

S C Goswami & Usha Goswami
National Institute of Oceanography, Dona-Paula, Goa, 403 004, India
Received 19 August 1991

Prawn larvae were studied to determine suitable lunar and tidal phases and time for large scale seed collection for prawn aquaculture. Larvae and postlarvae of 8 commercially important species were observed in the surface and bottom zooplankton samples. These were in order of abundance, Metapenaeus dobsoni (Miers), M. affinis (H. Milne-Edwards), M. monoceros (Fabricius), Parapeneopsis stylifera (H.Milne-Edwards), Penacus merguiensis De Man, P. indicus H. Milne-Edwards, P. monodon Fabricius and P. semisulcatus De Haan. The mysis stages were dominant. Water temperature and salinity variations were meagre and do not seem to influence larval abundance. However, lunar phases, diel cycles and tidal oscillations influenced their occurrence. The preponderance of protozoea and mysis stages was noticed in samples taken during day time while postlarvae were common at night. Total ingression of penaeid prawn larvae was more during full moon and hightide compared to new moon and low tide periods.

Prawns of family Penaeidae are of considerable importance in the fishery of the coastal and estuarine waters of India1. Their larvae ingress with tidal currents into estuarine and backwaters for feeding and growth. They later return to the coastal and marine habitats for spawning. The variations in the intensity of larvae recruitment determine the success of prawn capture fisheries in any particular region. The seasonal and diel recruitment patterns of penaeid prawn larvae in the estuaries of Goa were studicd2-4. The influence of lunar phases on penaeid prawn larval abundance in the estuaries along the east coast of India was documented^{5,6}. Information is not available on the influence of lunar phases on ingression of larvae and postlarvae into the estuarine ecosystems along the west coast except in Cochin backwaters7. The present paper deals with the relative occurrence and abundance of protozoea, mysis and postlarval stages of penaeid prawns during lunar, diel and tidal phases in the Mandovi estuary, Goa.

Materials and Methods

The study was carried out over entire tidal cycles during full moon (5-6 March 1985) and new moon (21-22 March 1985) periods at a station (2 km leewards from the mouth region) in the Mandovi estuary, Goa (lat. 15°30 N; long. 73°50 E). Surface and bottom (5 m depth) zooplankton samples were taken with HT net (mouth area 0.25 m² and mesh-

width 0.3 mm) fitted with a calibrated flowmeter. The sampling was done at every 2 h interval covering the entire tidal cycle. Penaeid prawn larvae were sorted from 25 to 100% of the sample. Their numbers were raised to total and given as 100 m⁻³. The larvae of each species were further sorted into 3 protozoea, 3 mysis and postlarval stages and identified⁸. Water samples were taken simultaneously along with zooplankton for measurements of temperature and salinity. To study diurnal variability the zooplankton and water collections made between 0600 to 1800 and 1800 to 0600 hrs were considered arbitrarily as day and night samples respectively.

Results and Discussion

Temperature and salinity variations over the entire diel cycles were not much (Table 1). The prevailing hydrographical conditions over the diel cycles do not seem to influence the larval abundance (Table 1) as reported earlier³. Larval stages of 8 penaeid prawn species were encountered. The protozoea, mysis and postlarval stages occurred in varying numbers (Table 2). Five eggs and 2 nauplii were obtained in the surface zooplankton sample taken at 1100 hrs on full moon day. Their number being negligible, these were not included in the total counts. The larval stages of various species recorded in the order of abundance were *Metapenaeus dobsoni* (36.2%), *M. affinis* (29.44%), *M. monoceros*

(12.25%) Parapeneopsis stylifera (7.06%), Penaeus merguiensis (4.76%), P. indicus (4.69%), P. monodon (2.96%) and P. semisulcatus (2.64%). Based on total larval counts, the mysis stages were abundant (48.91%), followed by protozoea (34.68%) and postlarvae (16.41%). Amongst the protozoea stages (Table 2) highest and lowest abundance were recorded for protozoea III and protozoea II respectively. The protozoea I were invariably present except for M. monoceros in bottom samples taken during full moon. The protozoea I of M. affinis were common but those of P. semisulcatus were poorly represented during both the lunar phases. The protozoea II of M. monoceros, P. merguiensis, P. semisulcatus and P. stylifera were not recorded in zooplankton samples collected during full moon but were present in varying numbers in new moon collections, except for P. merguiensis. The protozoea III were numerous and occurred invariably in all samples. The maximum and minimum occurrence were recorded for M. affinis and P. semisulcatus. Among the mysis stages, highest and the lowest population density were recorded for mysis I and mysis III respectively. The poor occurrence of mysis III could be that when the larvae reach this stage they sink to the bottom to take up the benthic mode of life. The occurrence and abundance (no. 100 m⁻³) of mysis stages were also influenced by the lunar phases, being comparatively more in zooplankton samples taken during full moon (14249) than during new moon period (3003). The mysis stages of M. dobsoni were common while those of

P. monodon were poorly represented and were not observed in surface collections taken on the new moon (Table 2). Earlier studies⁵⁻⁷ on the influence of lunar phases on ingression rates of penaeid larvae into the Indian estuarine ecosystems dealt mainly with the postlarval stages. No data is available for comparison with regard to protozoea and mysis stages from the Indian waters. However, Cockroft and Wooldridge9 reported that mysis I of Macropetasma africanus was the dominant constituent of penaeid prawn larval population during full moon in the Algoa Bay, S. Africa. During the present study the postlarvae of M. dobsoni, M. monoceros, P. stylifera, P. semisulcatus, P. merguiensis, M. affinis, P. monodon and P. indicus were obtained in order of abundance. Kuttyamma⁷ reported that the postlarvae of M. dobsoni were dominant and those of P. indicus were poorly represented in zooplankton collections from the Cochin backwaters. The postlarvae were encountered almost in all the collections, particularly during the new moon phase. It was reported that the larvae were abundant in collections during new moon9. Subramanyam and Rao10 observed no definite trend in the occurrence and abundance of postlarvae in samples collected coinciding with the full moon and new moon days. The numerical abundance of larvae varied with the type of haul, being abundant in the surface (61.92%) compared to bottom hauls (38.08%). In general the protozoea and mysis stages were common in the surface samples. The postlarvae were generally more in bottom collections during full moon. The postlarvae of

M. affinisand M. monoceros were abundant in surface collections irrespective of the lunar phase (Table 2).

Diel and tidal variations—Population density of larvae of penaeid prawn species varied with tidal cycle (Table 3). The larval stages of Metapenaeus dobsoni, M. monoceros and M. affinis were common in surface and bottom zooplankton samples collected during day. The postlarvae of genera Penaeus and

Parapeneopsis (Table 3) were abundant in surface samples taken at night. Nocturnal abundance in the distribution of penaeid larvae was reported from other areas^{5,10-12}. Higher occurrence of postlarvae in night collections in the Mandovi estuary was also reported³. Mandovi estuary is a tide dominated coastal plain estuary with semi-diurnal tides and with maximum amplitude of about 2 m. The tidal flow
