Abstract

We present high resolution paleosecular variation (PSV) records up to 8 cal. kyr BP from three piston cores, MD161/8, MD161/11 and MD161/13 acquired in the Krishna-Godavari (KG) basin, Bay of Bengal. During the Holocene period, high sedimentation rates are recorded at MD161/8 (38.8 – 248.3 cm/kyr), MD161/11 (137-336 cm/kyr) and MD161/13 (~573 cm/kyr). Rock magnetic data analysis suggests that the remanence signal is carried by titanomagnetite/ titanohematite grains in stable single domain (SSD) / pseudo single domain (PSD) state. The PSV records of MD161/11 and MD161/13 show good correlation in the uppermost sediments despite significant variation in the sedimentation rates; however, poor correlation of PSV records is observed for the core MD161/8 probably due to local effects. Paleoinclination records of MD161/8, MD161/11 and MD161/13 show a low between ~2.4-2.0 cal. kyr BP, an increase between 2.0-1.4 cal. kyr BP and a decrease towards the present. To varying degrees these trends can be observed in the other Asian PSV records of Shuangchiling (SCL) and Biwa lakes. However, the magnitude of the observed inclination anomaly in KG basin is higher (~40°) compared to those reported from SCL (~25°) and Biwa (~10°) lakes. Paleodeclination records of MD161/11 and MD161/13 show a decline between ~4.0-2.9 cal. kyr BP, an increase between 2.9-2.1 cal. kyr BP, a substantial decrease between ~2.1- 1.0 cal. kyr BP and an increase towards the present. Similar trends can be observed in the other Asian PSV records of SCL and Biwa lakes with a minor age offset of 0.2 to 0.5 kyr. The available models CALS7k.2 and CALS10k.1 are evaluated for their capability in predicting the inclination and declination anomalies from the Asian regions. The CALS7k.2 model can predict most of the inclination anomalies while the CALS10k.1 is unable to predict many of them. The CALS7k.2 model shows that the observed inclination anomalies can be attributed to the presence of a strong non-axial dipolar magnetic field over the Bay of Bengal. More PSV records need to be constructed to better understand the anomalous non-axial dipolar field over the Bay of Bengal.

1. Introduction

Paleomagnetic studies are being carried out worldwide to establish high resolution paleosecular variation (PSV) records that can be used to correlate regional stratigraphies (Turner and Thompson 1981, 1982; Hagstrum and Champion 2002; St-Onge et al., 2003; Snowball et al., 2007; Barletta et al., 2010a, 2010b, Snowball and Sandgren 2002; Lund and Banerjee 1985; Verosub et al., 1986; Creer and Tucholka 1982; Lisé-Pronovost 2009; Roberts et al., 2013) and to understand the geodynamo processes responsible for the Earth's magnetic field (Merril et al., 1996; McFadden and Merril, 1995). Historical observation of PSV data is available only for the last 400 years (Jackson et al., 2000). Prior to direct observations, the variation of Earth's magnetic field on millennial scale can be reconstructed using archeological materials and volcanic rocks as well as from rapidly deposited, well-dated lake/marine sedimentary sequences (e.g., Stockhausen, 1998; Ali et al., 1999; Frank et al., 2002; Vigliotti, 2006; Irurzun et al., 2006, 2008; Snowball et al., 2007). Most of the PSV records documenting the Holocene are from Europe (Vigliotti et al., 2006; Sagnotti et al., 2011; Stockhausen, 1998; Opdyke et al., 1972; Thompson 1975; Turner and Thompson 1981), North America (Creer and Tucholka 1982; Lund and Banerjee 1985; Verosub et al., 1986; Hanna and Verosub 1989; Sprowl and Banerjee, 1989; King 1983), central Asia (Gomez-Pâccard, 2012; Péck et al., 1996; Nurgaliev et al., 1996, Nourgaliev 2003) and South East Asia (Ali et al., 1999; Hyodo et al., 1999; Yang et al., 2009, 2013; Zheng et al., 2014). The scarcity of Holocene PSV records within 20° of the Equator limits our ability to understand time and space variability of the Earth's magnetic field and related geodynamo processes. Moreover, such high resolution PSV records are not available from the northern Indian Ocean. Therefore, we attempt to establish the high resolution and continuous PSV records from the high sedimentation regions of Krishna Godavari (KG) basin, Bay of Bengal, using three Calypso piston cores MD161/8 (~30 m, water depth= 1033 m, Lat=15° 51.8624'N, Lon=81° 50.0692'E) , MD161/11 (~28m, water depth= 1007 m, Lat= 15° 54.0217'N, Lon=81° 48.1366'E) and MD161/13 (~29 m, water depth=647 m, Lat=16° 01.9684'N, Lon=81° 42.7909'E) acquired onboard *M/V Marion Dufresne* in 2007. The PSV records are evaluated for their potential to act as a reliable tool for magnetic stratigraphy as well as to understand the geodynamo processes manifested over the Bay of Bengal.

2. Geology of the study area

Krishna Godavari (KG) basin is a petroliferous basin in the Bay of Bengal. It is a pericratonic rift basin formed due to the breakup of Gondwanaland around 130 Ma years ago (Sastri et al., 1981;

Rao, 2001; Powell et al., 1988; Scotese et al., 1988; Ramana et al., 1994). It encompasses an area of 28,000 sq. km onshore and 145,000 sq. km offshore (Ojha and Dubey, 2006) and stretches from the Ongole in south to the Vishakhapatnam in north. Thickness of onshore sediments varies between ~ 3 and 5 km which increases to ~8 km in offshore region (Prabhakar and Zutshi 1993; Bastia 2007). The thick sediment strata largely composed of montmorillonite clay (Rao, 1991) are brought by Krishna and Godavari rivers and their tributaries which originate in the Western Ghats and run over the provenance of Deccan trap basalts. Environmental magnetic studies by Sangode et al., (2007) showed higher magnetic susceptibility values in Godavari basin in comparison with those from other basins in Indian subcontinent.

The studied cores (MD161/8, MD161/11 and MD161/13) were acquired from the continental slope region of the KG basin (Fig. 1). Sedimentological studies show that the grain size of the sediment is predominantly clay (~70 %) and silt (~30 %) with traces of sand fraction (NIO, 2005). Further, X-Ray analysis of clay minerals suggests the presence of montmorillonite clay with traces of illite and kaolinite. The dominant detrital magnetic minerals, as evident from the SEM-EDS analysis of the magnetic extracts, are titanomagnetite and titanohematite with varying amount of Ti/Fe ratio from 0.2 to 0.45 (Dewangan et al., 2013, Usapkar et al., 2014). The presence of sub-surface hydrates is confirmed in the KG basin from drilling/coring activities during NGHP Expedition 01 (Kumar et al., 2014). Geophysical signatures associated with fluid/gas migration have also been documented in KG basin indicating migration of methane gas through the sediment (Ramana et al., 2009; Dewangan et al., 2010; Ramprasad et al., 2011). Geochemical signatures related to a paleo-cold seep activity are also reported in KG offshore basin (Mazumdar et al., 2009). The geochemical processes such as anaerobic oxidation of methane (AOM) may significantly alter the magnetic minerals and affect the magnetic measurements. The detailed rock magnetic measurements of the core MD161/8 reveal dissolution of magnetic minerals and authigenic growth of secondary iron sulfides below 7 m related to methane seep (Dewangan et al., 2013), and such diagenetically altered sediments are not considered in the present study.

3. Methodology

The cores MD161/8, MD161/11 and MD161/13 collected primarily for gas hydrate studies are used to reconstruct the PSV records in the Bay of Bengal. After retrieval, the core was split in two halves and was cut in to sections of length 1 to 1.5 m. About 20 cm sub-sampling was carried out immediately from each section for micro-biology and pore-water chemistry studies related to gas hydrates. Cores (MD161/8 and MD161/13) were subsampled at a resolution of 2 cm using 7 cm³

cylindrical vials for paleomagnetic investigations. The core MD161/11 was subsampled eight years later at a resolution of 5 cm to substantiate the results obtained from MD161/8 and MD161/13 cores. The orientation of the sample was fixed with respect to a reference line pre-marked along the length of the core liner. All remanent magnetisation values were measured on the discrete samples using a Molspin fluxgate spinner magnetometer. Paleomagnetic measurements on the sediment samples from MD161/8 core were carried out at the environmental magnetic laboratory, Indian Institute of Geomagnetism (IIGM), Panvel, India; whereas paleomagnetic measurements on the samples from MD161/11 and MD161/13 cores were carried out at paleomagnetic laboratory, National Institute of Oceanography (NIO), Goa, India. The samples from MD161/8 were progressively demagnetised using an alternating field (AF)-Demagnetiser from 0 to 100 mT in steps of 10 mT, and characteristic remanent magnetisation (ChRM), i.e., paleomagnetic inclination, declination and intensity as well as the maximum angle of deviation (MAD) were calculated by using Principal Component Analysis (PCA: Kirschvink, 1980). In case of MD161/13, one pilot sample per section (1.5 m) was progressively AF-Demagnetised from 0 to 40 mT in steps of 5 mT and then to 100 mT in steps of 10 mT. The analysis of demagnetisation results of pilot samples from MD161/13 suggests that the viscous component of NRM can be removed by applying 15 mT demagnetisation field. Therefore, the remaining samples of MD161/13 were demagnetised at 15 mT to obtain the paleomagnetic inclination, declination and intensity records. The samples from MD161/11 were progressively AF-Demagnetised from 0 to 50 mT in steps of 10 mT, and ChRM as well as MAD were calculated using PCA analysis. The paleointensity record for the cores is obtained by normalizing the respective NRM values by susceptibility and is shown in Figure 4C.

High resolution rock magnetic data of the sediment core MD161/8 have been reported by Dewangan et al. (2013). Following a similar methodology, rock magnetic measurements were carried out on wet samples at a resolution of 10 cm for MD161/13 core. Magnetic susceptibility measurements were performed using Bartington MS2B dual frequency susceptibility meter. Susceptibility was measured at two different frequencies $\chi_{LF} = 0.47$ kHz and $\chi_{HF} = 4.7$ kHz and the frequency dependent susceptibility was computed as $\chi_{fd\%} = (\chi_{HF} - \chi_{LF})/\chi_{LF} \times 100$. Anhysteric remanent magnetisation (ARM) was imparted using 100 mT AF field superimposed with a fixed DC bias field of 50 μ T. Susceptibility of ARM is calculated as mass normalized ARM divided by the DC bias field. Isothermal remanent magnetisation (IRM) of 1 T in forward direction and -20 mT, -30 mT, -100 mT and -300 mT in backward direction were imparted to the sediment samples using a MMP10 pulse magnetiser. Mass-normalized IRM acquired with a peak field of 1T is assumed to be the saturation isothermal remanent magnetization (SIRM). S-ratio is computed using formula (S-ratio = IRM.

$_{300\text{mT}}/\text{IRM}_{1\text{T}}$: Thompson and Oldfield, 1986; Bloemendal et al., 1988). Soft-IRM and Hard-IRM (HIRM) were computed using formulae [Soft-IRM= $(\text{IRM}_{1\text{T}} + \text{IRM}_{-30\text{mT}})/2$] and [HIRM= $(\text{IRM}_{1\text{T}} + \text{IRM}_{-300\text{mT}})/2$] (Liu et al., 2007).

4. Results

4.1 Paleomagnetic record

The AF-demagnetisation results of NRM were analysed using Zijderveld vector end point diagrams (Zijderveld, 1967). The Zijderveld plots of some of the samples from the MD161/8 (Fig. 2A), MD161/11 (Fig. 2B) and MD161/13 (Fig. 2C) show that the data points (≥ 20 mT) lie on a straight line trending towards the origin indicating the presence of stable ChRM. The inclination, declination and intensity records of MD161/8, MD161/11 and MD161/13 are shown in Figure 3A, 3B and 3C, respectively and the values are listed in Table-1. The sedimentation rates, as estimated from radiocarbon ages, are very high in the KG basin during Holocene and show significant temporal and spatial variations (Mazumdar et al., 2012). The topmost sediments (< 4 mbsf) of core MD161/8 show a very high sedimentation rate of 248 cm/kyr which decreases to 86.7 cm/kyr between 4 and 7 mbsf (Mazumdar et al., 2009). The uppermost 7 mbsf of MD161/8 covers the late Holocene period up to 8 cal. kyr BP. The PSV records of MD161/8 below 7 mbsf are excluded from the present study due to diagenesis of magnetic minerals owing to sulfidisation (Dewangan et al., 2013). The average sedimentation rate of MD161/13 is extremely high around 573 cm/kyr, and the top 22 m extends up to 4 cal. kyr BP (Mazumdar et al., 2012). A rapid increase in sedimentation rates below 22 mbsf possibly relates to reported mass transport deposits (MTD; Mazumdar et al., 2012); therefore, the magnetic records of MD161/13 below 22 m are excluded from the present study. The uppermost 8 mbsf of MD161/11 shows a sedimentation rate of 336 cm/kyr which decreases to 137 cm/kyr between ~8 and 13 mbsf. Rapid sedimentation is observed below 13 mbsf possibly associated with MTDs, therefore the PSV records below 13 mbsf are not used in the present study. The top 1.5 m of the sediment cores was highly disturbed due to piston coring, and is not used for NRM studies. Due to the vast differences in sedimentation rate, the PSV records are expressed in terms of age rather than depth to facilitate better comparison between the inclination (Fig. 4A), declination (Fig. 4B) and paleointensity (Fig. 4C) of cores MD161/8, MD161/11 and MD161/13.

In spite of the differences in the sedimentation rates, paleoinclination records of MD161/8, MD161/11 and MD161/13 show broad similarity in variation pattern (Fig. 4A). The paleoinclination records show significant fluctuations between -20° and 20° (approx.) for the uppermost sediment (<

4 cal. kyr BP) in contrast to the expected axial dipole field inclination of 30° at these locations. The core MD161/13 shows significantly low inclination values as compared to the expected value at 0.6, 2.2 and 3.8 cal. kyr BP, while low inclination values are observed at 2.0 and 5.8 cal. kyr BP for MD161/8. Similar low inclination values are also observed at ~2, 4.3 and 7 cal. kyr BP for MD161/11. Higher values of inclination (> 30°) are observed at 1.4 cal. kyr BP for cores MD161/11, MD161/13 and possibly for core MD161/8.

The paleodeclination profiles of MD161/8, MD161/11 and MD161/13 represent relative variations in declination as the cores were not oriented with respect to geographic north. The relative paleodeclination of MD161/8 is obtained from ChRM declination by subtracting an arbitrary constant of 180° so that it fluctuates around zero. No correction was applied for the relative paleodeclination of MD161/13. An arbitrary constant of 250° was subtracted from paleodeclination values of MD161/11. The relative paleodeclination of MD161/11 and MD161/13 shows a broad similarity pattern from 5.4 cal. kyr BP to Recent (Fig. 4B). An increase in declination is observed between 5.4 and ~4.3 cal. kyr BP in MD161/11 core. A gradual decrease in declination is observed between 4.3 and 2.9 cal. kyr BP in MD161/11 and MD161/13 cores. The declination further increases with minor oscillations between 2.9 and ~2.0 cal. kyr BP. The sharp decrease of declination by about 100° is observed from 2.0 to 1.0 cal. kyr BP. Further, an increasing trend is observed towards Recent in core MD161/13. The declination profile of MD161/8 shows essentially no trend over most of the time interval, however it depicts a decline in paleodeclination between 2 and ~1.4 cal. kyr BP as observed in cores MD161/11 and MD161/13.

An increase in paleointensity is observed between ~6 and ~4 cal. kyr BP in MD161/8 and MD161/11 cores. A gradual decrease is observed between 4 and 3 cal. kyr BP in MD161/11 and MD161/8 cores, while the trend is reverse in MD161/13 core. Further, a constant trend with minor undulations is observed towards Recent in all the cores. Overall, the paleointensity records of MD161/8, MD161/11 and MD161/13 are poorly correlated and probably reflect the variation in the concentration, grain size and mineralogy of the magnetic minerals. Therefore, the paleointensity records are not utilised for interpretation in the present study.

4.2 Rock magnetism: Magnetic mineral concentration and magnetic granulometry

The detailed rock magnetic parameters for the core MD161/8 have been reported by Dewangan et al. (2013). In the present study, the rock magnetic studies related to the core MD161/13 was carried out and the results are presented in Table 2. The average values and standard deviation of different rock

magnetic parameters for MD161/13 and MD161/8 cores are listed in Table 3. The magnetic parameters χ , ARM and SIRM are mainly related to the concentration of magnetic minerals while ARM is sensitive to single domain (SD) and pseudo-single domain (PSD) grains. The χ_{LF} and SIRM are also sensitive to coarser grain sizes of magnetic minerals mainly in the multidomain (MD) state (Dunlop 1973; Bailey and Dunlop 1983; Thompson and Oldfield, 1986). In general, a trend of down core decrease is observed for the parameters χ_{LF} , χ ARM, and SIRM suggesting gradual reduction in the abundance of magnetic minerals (Fig. 5A-C). A minor increase in χ_{LF} and SIRM is observed between 2.5 and 3.5 cal. kyr BP. A similar increase is also seen in χ ARM over the same time interval. This reflects the possible occurrence of relatively higher proportion of finer magnetic grains (SSD/PSD) in this interval.

The interparametric ratios ARM/SIRM, SIRM/ χ_{LF} and $\chi_{fd}\%$ are regarded as potential magneto-granulometric indicators while S-ratio depends on the magnetic minerals. The soft- and hard-IRM values reflect the abundance of soft and hard magnetic minerals, respectively (Banerjee et al., 1981; Maher, 1988; Oldfield, 1994). The $\chi_{fd}\%$ values for the majority of the samples are < 5 % indicating minor contributions from superparamagnetic (SP) particles (Fig. 6A). The ARM/SIRM and $\chi_{fd}\%$ show gradual downcore increase from present to 2.8 cal. kyr BP indicating the relative increase in the abundance of fine grained magnetic minerals (Fig. 6 A, B). Further downcore (> 2.8 cal. kyr BP), a decrease in ARM/SIRM and $\chi_{fd}\%$ as well as the increase in SIRM/ χ_{LF} (Fig. 6C) can be attributed to the coarsening of magnetic grains. The S-ratio is close to 0.95 indicating the dominance of soft magnetic minerals (Fig. 6D). Soft-IRM and hard-IRM values (Fig. 6E and Fig. 6F) show a gradual decreasing trend downcore; however, a minor increase in hard-IRM values is observed between 3 and 3.2 cal. kyr BP.

5. Discussion

5.1. Assessment of the quality of PSV records: Pros, cons and limits

A good quality high resolution PSV record requires a continuous core from a high sedimentation region. High concentration of unaltered magnetic minerals in a stable single domain (SSD) / pseudo single domain (PSD) state is a pre-requisite for stable remanent magnetisation. High influx of magnetic minerals owing to high sedimentation rates provides an ideal geological environment to construct PSV records. The sedimentation rates (SRs) in the shelf and slope regions of KG basin are high; average SR for core MD161/13 is 573 cm/kyr and the SRs for the upper most 7 m of core MD161/8 range from 86.7 to 248 cm/kyr. A variable sedimentation rate of 336 cm to 137 cm/kyr is

observed for upper 13 m of core MD161/11 (Mazumdar et al., 2012). Previous environmental magnetic studies by Sangode et al. (2007) showed that Godavari basin receives huge concentrations of magnetic minerals from Deccan flood basalts, and possesses high magnetic susceptibility in comparison with other depositional environments from Indian subcontinent. Therefore, the sediment cores retrieved from this basin were investigated to construct high resolution PSV records. The other factors which could also potentially influence the reliability of PSV records are the variability in magnetic mineral concentration, magnetic grain size and mineralogy. Hence these parameters are also studied to assess the reliability of PSV records.

The X-Ray diffraction (XRD) analysis of magnetic extracts suggests that the dominant magnetic mineral is titanomagnetite in the study area (Dewangan et al., 2013; Usapkar et al., 2014). Detailed magnetic measurements are carried out for core MD161/13 to understand the magnetic mineralogy, concentration, grain size and the signatures associated with reductive dissolution of magnetic minerals. The downcore decrease in parameters χ_{LF} , χ_{ARM} and SIRM of MD161/13 (Fig. 5) suggests reduction in the concentration of the magnetic minerals with depth due to sulfidisation (Peketi et al., 2015). The values of χ_{ARM} gradually increase from 4 to 3 cal. kyr BP, thereafter remain almost constant until Recent. High values of χ_{ARM} suggest the presence of magnetic grains in SSD/PSD state which are capable of acquiring stable NRM. The low values of $\chi_{fd\%}$ (Fig. 6A) suggest a minor presence of SP grains. The grain size dependent ratios ARM/SIRM and SIRM/ χ_{LF} (Fig. 6B, C) suggest a uniform SSD/PSD magnetic grain size from 3 cal. kyr BP to present. A gradual down core increase in SIRM/ χ_{LF} ratio (> 2.5 cal. kyr BP) suggests higher abundance of PSD grains as compared to the SSD grains. An abrupt increase in SIRM/ χ_{LF} ratio around 2.5 cal. kyr BP may indicate the presence of SSD greigite (Roberts et al., 1996; Snowball 1997; Walden et al., 1999). The average S-ratio of core MD161/13 is around 0.95 indicating a uniform mixture of titanomagnetite and titanohaematite minerals (Thompson and Oldfield 1986; Bloemendal et al., 1992; St-onge et al., 2003; Heslop 2009). The Soft –IRM and hard-IRM values represent relative concentration of low coercivity titanomagnetite and hard coercivity titanomagnetite and/or titanohematite, respectively.

Similarly, the magnetic parameters (χ_{LF} , χ_{ARM} , SIRM) of core MD161/8 show a decreasing trend for the topmost sediments (< 7 mbsf) owing to the sulfidisation (Dewangan et al., 2013). The downcore decrease in SIRM/ χ_{LF} ratio for the uppermost sediments (< 5 mbsf) suggests a relative downcore increase in the concentration of SSD particles. An abrupt decrease in S-ratio around 5 cal. kyr BP indicates an increase in the abundance of titanohaematite.

The magnetic parameters χ and SIRM relate to the concentration of ferrimagnetic mineral components while S-ratio and HIRM are indicative of magnetic mineralogy. The cross plots between SIRM and χ for MD161/8 (Fig. 7A) and MD161/13 (Fig. 7B) show several different slopes and trends within each data set suggesting downcore variations in composition, grain size and concentration. The details of the rockmagnetic analysis on the studied cores confirm the presence of detrital ferrimagnetic minerals (titanomagnetite) in the SSD/PSD state. Therefore, the cores are suitable for PSV studies. However, the abrupt change in magnetic mineralogy as inferred from the S-ratio should be taken into account while interpreting the PSV records.

5.2 Intrasite reproducibility of PSV records and regional correlation

In order to test the reliability and reproducibility, PSV records of MD161/8, MD161/11 and MD161/13 are compared, and later they are correlated with similar records from the nearby Asian regions Shuangchiling (SCL) Hainan, south east of China (Lat: 19°N, Lon: 110°E; Yang et al., 2009) and Biwa lake (lat: 35°N, Lon: 110°E; Ali et al., 1999), Japan. Smoothed Paleoinclination records of MD161/8 (5 pt average), MD161/11 (5 pt average) and MD161/13 (9 pt average) show broad similarity despite significant variations in the sedimentation rates (Fig. 8A). Paleoinclination records of MD161/8, MD161/11 and MD161/13 show a low between ~2.4-2.0 cal. kyr BP, an increase between 2.0-1.4 cal. kyr BP and a decrease towards the Recent. To varying degrees similar trends in paleoinclination can also be observed in other two Asian records of SCL and Biwa lakes with a minor age offset of 0.2 to 0.5 cal. kyr. The strong low in paleoinclination observed in MD161/8 at 5.8 cal. kyr BP cannot be identified in other records; therefore it may be related to local effects. The inclination anomaly at ~4.3 cal. kyr BP is prominent in core MD161/11, but cannot be identified on MD161/8 core. An increasing trend in core MD161/13 between 4.0-2.4 cal. kyr BP probably relates to 4.3 cal. kyr BP anomaly. This low is also identified in SCL and Biwa lake records with a minor age offset. The magnitude of the inclination anomalies (~40°) as observed in the Bay of Bengal is higher than that of SCL-lake (~25°) and Biwa lake (~10°). It is interesting to note that the magnitude of inclination anomaly appears to be increasing towards the low-latitude regions. The consistency and correlability in the paleoinclination records on a broader scale among the three Asian regions suggests that the PSV records of Bay of Bengal can be reliable and thus be used to understand the geo-dynamo processes in Bay of Bengal. They can also act as reference curves, and the observed inclination anomalies can be used for site-to-site correlation and for relative dating during Holocene.

Paleodeclination records of MD161/11 and MD161/13 depict a decline between ~4.0-2.9 cal. kyr BP, an increase between 2.9-2.1 cal. kyr BP, a significant decrease between ~2.1- 1.0 cal. kyr BP and

an increase towards the present. In general, the smoothed paleodeclination patterns from 4.0 cal. kyr BP to Recent of MD161/11 and MD161/13 cores in Bay of Bengal are similar to other Asian records of SCL and Biwa lakes (fig. 8B). However, records from the Bay of Bengal show a larger swing in relative paleodeclination as compared to that of SCL and Biwa lakes. An increase in paleodeclination is observed between 5.4 - 4.5 cal. kyr BP for core MD161/11 which matches well with records of SCL and Biwa lakes with a minor age offset. Inconsistent paleodeclination trend is also observed among the Asian cores from 8-5.8 cal. kyr BP which may be attributed to the twisting/turning of the core during piston coring process (Ali et al., 1999). Also, the splitting of the core along the marked reference line may introduce some errors in the observed declination values. It may also happen that the differences in trend may be of geomagnetic origin owing to local effects (Frank et al., 2002).

5.3 Modeling and analysis of the observed inclination anomaly

In order to understand the governing factors for the observed inclination anomaly in the Asian records, the paleoinclination records of Asian records are compared with those computed from the available CALS7k.2 and CALS10k.1b models (Korte et al., 2005; Korte et al., 2011). The model represents time and space variability of paleo-geomagnetic field using spherical harmonics. The coefficients of spherical harmonics are obtained from published PSV records for the past 10 kyr (8000 BC to 1990 AD). The paleoinclination records from CALS7k.2 model at the locations of MD161/8, MD161/11, MD161/13, SCL and Biwa lakes (Fig. 8A) show lower inclination values at 0.4, 2.2, 4.3 and 5.8 cal. kyr BP as compared to the expected value. The observed data at these locations also show similar lows in inclination at 0.6, ~2.2 and 4.3 cal. kyr BP; however, the magnitude of the observed anomalies in Bay of Bengal is stronger. In contrast, the CALS10k.1b model is predicting higher inclination values at 2.2, 4.3 and 5.8 cal. kyr BP which is not supported by the data from the Asian regions.

The non-axial dipolar (NAD) inclination anomaly, defined as the difference between the modeled inclination with all coefficients and that predicted by the axial dipole coefficient, is computed for both CALS7k.2 and CALS10k.1b models at specific time intervals 0.6, 2.2, 4.3 and 5.8 cal. kyr BP (Fig. 9) to understand its effect over the Bay of Bengal. The inclination anomaly due to non-axial dipolar field as predicted by CALS7k.2 model is strongest over the Bay of Bengal at these time intervals (Fig. 9A). The correlation between the observed and modeled data suggests that the observed inclination anomaly may be related to the non-axial dipolar components of the Earth's magnetic field. In contrast, the CALS10k.1b model depicts an opposite trend in the temporal

variation of non-axial dipolar field in the Asian region (Fig. 9B) and is not consistent with the observed data. In fact, the average non-axial dipolar anomaly during the Holocene period shows a negative inclination anomaly over the Asian region from CALS7k.2 model and positive inclination anomaly from CALS10k.1b model (Korte et al., 2011).

The effect of non-axial dipolar field seems to be stronger over the Bay of Bengal as compared to other Asian regions like China or Japan which may explain higher intensity anomalies as observed in the present study. The initial results from KG basin show abnormal behavior of the geomagnetic field over the Bay of Bengal. Therefore, more PSV records from the high sedimentation regions of the Indian Ocean are required to understand the geodynamo processes over Bay of Bengal.

Conclusion

In the present study, PSV records are studied from KG basin, Bay of Bengal, for the past 8 cal. kyr BP. High sedimentation rates and continuous deposits with good age control provide good correlation in both inclination and declination records between the cores MD161/11 and MD161/13. Poor correlation is observed for the core MD161/8 which may be related to local effects. Interestingly, the PSV records from KG basin show a pattern similar to that observed from other Asian sites. Four major paleoinclination anomalies are observed at 0.6, 1.4, 2.2 and 4.3 cal. kyr BP in the Bay of Bengal. The lows in paleoinclination at 0.6, 2.2 and 4.3 cal. kyr BP are also predicted by CALS7k.2 model, but the intensity of the observed anomalies is stronger than that predicted by the model. Further, these inclination anomalies may be related to non-axial dipolar components of the Earth's magnetic field centered over the Bay of Bengal. The PSV record can be used for regional correlation as well as for relative dating of the Holocene sediments.

Acknowledgements

We thank the Director, CSIR-NIO for his support and permission to publish the paper. We also thank the Directors of NIOT and NCAOR, and the Secretary, Ministry of Earth Sciences for providing financial support for sediment coring onboard RV *Marion Dufresne*. The crew and officers of the RV *Marion Dufresne*, scientific and technical staff from NIO, NIOT and NGRI, and students from Goa University are also acknowledged for their support during the acquisition of cores. We would like to thank Daryl Vaz for preparing the final figures and Satyendra Singh Panwar for modeling the geomagnetic field. We like to thank Prof. Akira Hayashida, Drs. M. Ali and Hirokuni Oda for providing data of PSV records of Biwa lake and Prof. Yang Xiaoqiang for sharing the data from SCL lake. We thank the anonymous reviewers for their valuable suggestions which have improved the quality of the manuscript. VNJCT fellowship to Ms. Asha Usapkar is sincerely acknowledged. This is CSIR-NIO contribution no xxx.

Table 3: Average values and standard deviation of different rock magnetic parameters of MD161/13 and MD161/8.

Magnetic Parameters	Average Value (Mean) MD 13	Std Dev MD 13	Average Value (Mean) MD 8	Std Dev MD 8
$\chi_{LF} \times 10^{-6} \text{ m}^3 \text{kg}^{-1}$	0.966	0.155	1.185	0.276
$\chi_{fd\%}$	3.235	0.664	5.163	1.037
$\chi_{ARM} \times 10^{-5} \text{ m}^3 \text{kg}^{-1}$	0.865	0.115	0.849	0.180
SIRMx $10^{-5} \text{ Am}^2 \text{kg}^{-1}$	1780.432	289.095	1466.577	353.556
Soft-IRMx $10^{-5} \text{ Am}^2 \text{kg}^{-1}$	754.097	121.166	1236.317	290.369
Hard-IRM (Hirm)x $10^{-5} \text{ Am}^2 \text{kg}^{-1}$	47.737	13.803	86.800	87.213
S-ratio	0.946	0.014	0.940	0.054
ARM/SIRM	0.020	0.002	0.024	0.004
SIRM/ χ kAm $^{-1}$	18.509	1.450	12.409	1.060
